The immune system is capable of recognising and eliminating tumour cells, however as this process can break time, this may lead to the progression of cancer. Through the use of data sets comprising certain genetic biomarkers in addition to various genomic techniques, the researchers were able to determine the outcome and characterise T cells in tumours, describing how they develop. They showed that T cells develop in different ways. Following early activation, some T cell activity ceases and they convert to memory T cells instead of the, thought to be the only path, T cell exhaustion. Interestingly, the enrichment of these T cells positively correlates with successful response to immune checkpoint blockade therapy, a form of immunotherapy, as well as patient survival.

The present study presents findings that may lead to the improvement of therapeutics.
